Abstract. We present a first description and evaluation of GEOS-CHEM, a global three-dimensional (3-D) model of tropospheric chemistry driven by assimilated meteorological observations from the Goddard Earth Observing System (GEOS) of the NASA Data Assimilation Office (DAO). The model is applied to a 1-year simulation of tropospheric ozone-NO_x-hydrocarbon chemistry for 1994, and is evaluated with observations both for 1994 and for other years. It reproduces usually to within 10 ppb the concentrations of ozone observed from the worldwide ozonesonde data network. It simulates correctly the seasonal phases and amplitudes of ozone concentrations for different regions and altitudes, but tends to underestimate the seasonal amplitude at northern midlatitudes. Observed concentrations of NO and peroxyacetylnitrate (PAN) observed in aircraft campaigns are generally reproduced to within a factor of 2 and often much better. Concentrations of HNO₃ in the remote troposphere are overestimated typically by a factor of 2–3, a common problem in global models that may reflect a combination of insufficient precipitation scavenging and gas-aerosol partitioning not resolved by the model. The model yields an atmospheric lifetime of methylchloroform (proxy for global OH) of 5.1 years, as compared to a best estimate from observations of 5.5 ± 0.8 years, and simulates H₂O₂ concentrations observed from aircraft with significant regional disagreements but no global bias. The OH concentrations are ~20% higher than in our previous global 3-D model which included an UV-absorbing aerosol. Concentrations of CO tend to be underestimated by the model, often by 10–30 ppb, which could reflect a combination of excessive OH (a 20% decrease in model OH could be accommodated by the methylchloroform constraint) and an underestimate of CO sources (particularly biogenic). The model underestimates observed acetone concentrations over the South Pacific in fall by a factor of 3; a missing source from the ocean may be implicated.

1. Introduction

Global three-dimensional (3-D) models of tropospheric chemistry are fast becoming standard tools for improving our knowledge of chemical budgets and processes in the troposphere. They are also beginning to be used in an exploratory way to provide chemical forecasts for experimental field programs [Flato *et al.*, 2000], to provide *a priori* for satellite retrievals [Palmer *et al.*, 2001], to

examine aerosol-chemistry-climate interactions [Roelofs *et al.*, 1997; Mickley *et al.*, 1999; Adams *et al.*, 2001], and to guide international environmental policy assessments [Intergovernmental Panel on Climate Change (IPCC), 1995, 2001]. Several community intercomparisons of global tropospheric chemistry models have been conducted recently, demonstrating the rapid growth of the field [Jacob *et al.*, 1997; Kanakidou *et al.*, 1999; Rasch *et al.*, 2000; IPCC, 2001].

A central theme in the development of global tropospheric chemistry models is the simulation of ozone-NO_x-hydrocarbon chemistry. Better understanding of the factors controlling tropospheric ozone is a major research priority [World Meteorological Organization (WMO), 1998]. More generally, ozone-NO_x-hydrocarbon chemistry determines radical and oxidant processes in the troposphere and lies therefore at the heart of most problems affecting tropospheric composition. Simulation of ozone-NO_x-

Figure 1. Sigma vertical levels in successive generations of the GEOS assimilated meteorological data. The GEOS-1 data (1985-1995) have 20 levels from the surface to 10 hPa; the GEOS-STRAT data (1996-1997) have 46 levels from the surface to 0.1 hPa; the GEOS-2 data (1998-1999) have 70 levels from the surface to 0.01 hPa; the GEOS-Terra data (2000-) have 48 levels from the surface to 0.01 hPa.

hydrocarbon chemistry is difficult in a global model because of the large number of species involved (~ 100), the nonlinearity of the chemistry, the numerical stiffness of the system, and the coupling of chemistry to transport over a wide range of scales. A number of independently developed models have been reported in the literature over the past few years [e.g., Collins *et al.*, 1997; Brasseur *et al.*, 1998; Wang *et al.*, 1998a; Lawrence *et al.*, 1999; Levy *et al.*, 1999; Lelieveld and Dentener, 2000]. They share similar theoretical foundations but differ in many ways including resolution, the driving meteorological fields, and the approaches and detail for simulating emissions, chemical processes, and deposition.

Our first-generation global model of tropospheric ozone- NO_x -hydrocarbon chemistry was described and evaluated by Wang *et al.* [1998a, 1998b] and subsequently refined by Horowitz and Jacob [1999] and Mickley *et al.* [1999]. It uses meteorological fields from a general circulation model (GCM) developed at the Goddard Institute of Science Stud-

ies (GISS) [Hansen *et al.*, 1983; Rind and Lerner, 1996]. We have since developed the need for a model driven by assimilated meteorological observations in order to provide better constraints on the simulation of specific years, to allow investigations of interannual variability, and to set in place a machinery to conduct chemical forecasts in support of aircraft missions.

We present here our second-generation global model using assimilated meteorological data from the Goddard Earth Observing System (GEOS) of the NASA Data Assimilation Office (DAO) [Schubert *et al.*, 1993]. Development of this second-generation model involved the grafting of the Wang *et al.* [1998a] modules of photochemistry, emissions and deposition onto the original GEOS chemical transport model developed by Allen *et al.* [1996a, 1996b] and Lin and Rood [1996]. We give in the present paper a general description and evaluation of the resulting model, which we call GEOS-CHEM, focusing on tropospheric ozone- NO_x -hydrocarbon chemistry. This paper is intended to provide background for

several recent and ongoing studies using the GEOS-CHEM model [Singh *et al.*, 2000a; Li *et al.*, 2000; Palmer *et al.*, 2001; Liu *et al.*, 2001; Bey *et al.*, this issue].

2. Model Description

2.1. Model Framework

The GEOS assimilated meteorological observations used to drive the GEOS-CHEM model are available as a continuous archive from 1985 to present, with 3- or 6- hour temporal resolution depending on the variable. The GEOS assimilation system has gone through successive generations: GEOS-1 (1985-1995), GEOS-STRAT (1996-1997), GEOS-2 (1998-1999), and GEOS-Terra (2000-). The horizontal resolution is 1° latitude by 1° longitude in GEOS-Terra and 2° latitude by 2.5° longitude in earlier versions. Meteorological fields are provided on a sigma coordinate with 20 vertical levels in GEOS-1, 26 in GEOS-STRAT, 70 in GEOS-2, and 48 in GEOS-Terra (Figure 1). The GEOS-CHEM model is presently used at Harvard with either GEOS-1, GEOS-STRAT, or GEOS-Terra products. Table 1 lists the GEOS variables used as input to the model. For computational expediency we frequently merge levels in the stratosphere and average the data horizontally over a 4°×5° grid. The model transports 24 chemical tracers to describe tropospheric O₃-NO_x-hydrocarbon chemistry

(Table 2). Advection is computed every 15 min (2°×2.5° horizontal resolution) or 30 min (4°×5° horizontal resolution) with a flux-form semi-Lagrangian method described by Lin and Rood [1996]. Moist convection is computed using the GEOS convective, entrainment, and detrainment mass fluxes as described by Allen *et al.* [1996a, 1996b]. We assume full mixing within the GEOS-diagnosed atmospheric mixed layer generated by surface instability.

2.2. Emissions

We present in this paper a simulation for 1994, and emissions for that year are given in Table 3. Simulations for other years use adjusted anthropogenic emissions, as described below.

2.2.1. Anthropogenic emissions Simulation of specific years with a global tropospheric chemistry model must take into account the year-to-year variability of anthropogenic emissions. We use a base emission inventory for 1985 described by Wang *et al.* [1998a] that includes NO_x emissions from the Global Emission Inventory Activity (GEIA) [Benkovitz *et al.*, 1996], nonmethane hydrocarbon (NMHC) emissions from Piccot *et al.* [1992], and CO emissions developed at Harvard. We scale these emissions for specific years as follows. For unregulated countries (where no regulations have been imposed to limit emissions), NO_x emissions are scaled using trends in CO₂ emissions from

Table 1. GEOS Fields Used as Input to the GEOS-CHEM Model

Variable	Resolution ^a	Application
Wind vector	Inst 6 h	advection
Surface pressure	Inst 6 h	advection
Wet convective mass flux, detrainment ^b	Avg 6 h	convection
Mixed layer depth	Avg 3 h	boundary layer mixing
Temperature	Inst 6 h	chemistry
Specific humidity	Inst 6 h	chemistry
Cloud optical depth ^b	Avg 6 h	photolysis
Surface albedo	Inst 6 h	photolysis, dry deposition (snow cover)
Land-Water indices	Inst 6 h	dry deposition, lightning
Sensible heat flux	Avg 3 h	dry deposition
Solar radiation flux at surface	Avg 3 h	dry deposition
Surface air temperature	Avg 3 h	dry deposition, biogenic emissions
Surface wind (10 m altitude)	Avg 3 h	dry deposition, NO _x soil emissions
Friction velocity	Avg 3 h	dry deposition
Roughness height	Avg 3 h	dry deposition
Water condensation rate ^c	Avg 6 h	wet deposition
Total precipitation at the ground	Avg 3 h	wet deposition
Convective precipitation at the ground	Avg 3 h	wet deposition
Column cloud fraction ^d	Avg 3 h	biogenic emissions

^aThe fields are given with three different temporal resolutions. "Inst 6 h" indicates that the quantity is an instantaneous value given every 6 hours. "Avg 6 h" and "Avg 3 h" indicate that the quantity is averaged over 6 and 3 hours, respectively.

^bVertically resolved.

^cActually provided as the change in specific humidity due to moist processes. Interpretation as a water condensation rate is approximate [Liu *et al.*, 2001].

^dUsed to separate the direct and diffuse photosynthetically active radiation (PAR) in the calculation of isoprene emissions.

Table 2. Tracers for GEOS-CHEM Model Simulation of Tropospheric Ozone-NO_x-Hydrocarbon Chemistry

Tracer	Composition
O _x	O ₃ + O + NO ₂ + 2×NO ₃

R4N2	lumped alkyl nitrates

^a Other than peroxyacetyl nitrate (PAN) and peroxymethacryloyl nitrate (MPAN).

fossil fuel combustion, and CO and NMHC emissions are scaled using trends in CO₂ emissions from liquid fuels. Yearly CO₂ emissions for individual countries are provided by *Marland et al.* [1999], who primarily used energy statistics published by the United Nations [1998]. For regulated countries we use other emission inventories such as those provided by the Environmental Protection Agency (EPA) for the United States [EPA, 1997] and the European Monitoring and Evaluation Program (EMEP) for European countries [EMEP, 1997]. Table 4 shows the evolution of CO and NO_x emissions between 1985 and 1994 for different geopolitical regions. Global CO and NO_x emissions show little change over the years, but European emissions decrease while emissions in Asia, Africa, and Oceania increase. The large decrease of emissions in Europe after 1991 is due to regulatory control but also to the collapse of the former USSR. The largest increase of emissions occurs in Asia.

2.2.2. Biomass burning emissions Biomass burning and wood fuel emissions are from a climatological inventory previously described by *Wang et al.* [1998a]. This inventory includes different categories of burning (forest wildfires, tropical deforestation, slash-and-burn agriculture, savanna burning, and burning of agriculture waste), and yields a global CO emission of 520 Tg CO yr⁻¹. Emissions of NO_x and hydrocarbons are derived from the CO inventory using emission ratios as described by *Wang et al.* [1998a]. Wood fuel emissions of CO account for an additional total of 133 Tg CO yr⁻¹.

2.2.3. Biogenic emissions Isoprene emission rates from vegetation in the *Wang et al.* [1998a] model were computed with a modified version of the GEIA inventory [Guenther *et al.*, 1995], the principal modifications being a decrease in the leaf area index (LAI) from tropical forests and an improved representation of light attenuation within the forest canopy. We have made here some additional modifications. On the basis of recent estimates of isoprene fluxes for tropical vegetation [Klinger *et al.*, 1998; Helmig *et al.*, 1998], and also to improve agreement between simulated and observed isoprene concentrations, we have reduced emission rates for several ecosystems (tropical rain forest, tropical montane, tropical seasonal forest, dry taiga) by a factor of 3. This leads to a global emission rate for isoprene of 397 Tg C yr⁻¹. A biogenic source of acetone scaled to isoprene emissions was previously included by *Wang et al.* [1998a]. Because monoterpene oxidation has since been recognized to represent a major source of acetone [Reissel *et al.*, 1999], we now distribute biogenic emissions of acetone (15 Tg C yr⁻¹) following the pattern of monoterpene emissions [Guenther *et al.*, 1995] rather than isoprene emissions. Monoterpene emissions are not directly included in the model because their effect on global ozone chemistry is minimal.

2.3. Chemistry

The chemical mechanism for the troposphere includes 80 species and over 300 reactions with detailed pho-

Table 3. Global Emissions for 1994 in the GEOS-CHEM Model

Species	Emission Rate
NO_x , Tg N yr ⁻¹	
Fossil fuel combustion	22.8
Biomass burning	12
Soil	6.7

Oceania	9.0	10.0	11.0
Total	392.5	398.0	388.0

Anthropogenic emissions include fossil fuel combustion and industrial sources. North America includes the United States and Canada. South America includes also Central America. Europe includes the former USSR. Africa includes the Middle East. Oceania includes Australia, Indonesia and New Zealand.

tooxidation schemes for major anthropogenic hydrocarbons and isoprene, as described by Horowitz *et al.* [1998]. It has been updated with recent experimental data from DeMore *et al.* [1997], Atkinson [1997] and Brown *et al.* [1999a,1999b]. We have also changed the fate of the hydroxy organic nitrates produced by isoprene oxidation. Because these compounds are now believed to decompose quickly to HNO₃ on surfaces [Chen *et al.*, 1998], we assume direct formation of HNO₃ instead of the organic nitrates. The effect of heterogeneous chemistry on tropospheric ozone has been reviewed by Jacob [2000]. Following his recommendations, we include four reactions: NO₂ → 0.5 HNO₃ + 0.5 HNO₂, NO₃ → HNO₃, N₂O₅ → 2 HNO₃, and HO₂ → 0.5 H₂O₂ + 0.5 O₂, using reaction probabilities of 10⁻⁴ for NO₂, 10⁻³ for NO₃, 0.1 for N₂O₅, and 0.2 for HO₂. Aerosol surface areas are estimated on the basis of global 3-D sulfate concentration fields with monthly resolution from Chin *et al.* [1996], as described by Wang *et al.* [1998a].

Photolysis frequencies in the troposphere are calculated with the Fast-J algorithm of Wild *et al.* [2000], which uses a seven-wavelength quadrature scheme and accounts accurately for Mie scattering by clouds. Surface albedo and vertically resolved cloud optical depths are taken from the GEOS meteorological archive with 6-hour resolution. The model as described here uses climatological ozone concentrations as a function of latitude, altitude, and month to calculate the absorption of UV radiation by ozone. In more recent work, we have developed the capacity to use ozone column information for the specific year of simulation.

The chemical mass balance equations are integrated every hour using a Gear algorithm [Jacobson and Turco, 1994] for all grid boxes below the tropopause. The tropopause is diagnosed in the model using the standard criterion of a 2 K km⁻¹ lapse rate. Above the tropopause we use a simplified chemical representation which includes production of reactive nitrogen oxides (NO_y) from N₂O oxidation, production of CO and formaldehyde from CH₄ oxidation, and losses of tracers by reaction with OH or photolysis. Stratospheric production rates of NO_y, OH concentration fields, and NO_x/HNO₃ concentration ratios used to partition NO_y are monthly means provided by the 2-D model of Schneider *et al.* [2000]. Photolysis frequencies in the stratosphere are computed with a standard radiative transfer model [Logan *et al.*, 1981]. The resulting cross-tropopause NO_y flux is 0.65 Tg N yr⁻¹ (including 0.17 Tg N yr⁻¹ as NO_x and 0.48 Tg N yr⁻¹ as HNO₃). The main purpose of this simplified stratospheric chemistry is to account for decay of tropospheric tracers transported in the stratosphere, and to provide a source of NO_y to the troposphere. Cross-tropopause transport of ozone produced in the stratosphere requires a special treatment, as described in section 2.5.

2.4. Deposition

Dry deposition of oxidants and water soluble species is computed using a resistance-in-series model based on the original formulation of Wesely [1989] with a number of

modifications [Wang *et al.*, 1998a]. The dry deposition velocities are calculated locally using GEOS data for surface values of momentum and sensible heat fluxes, temperature, and solar radiation. Wet deposition (applied to HNO₃ and H₂O₂ only) includes scavenging by convective updrafts and anvils and by large-scale precipitation; this algorithm was developed by Liu *et al.* [2001], who evaluated it in the GEOS-CHEM by simulation of the aerosol tracers ²¹⁰Pb and ⁷Be.

2.5. Cross-Tropopause Flux of Ozone

Our initial approach to simulate the cross-tropopause ozone flux was to specify ozone concentrations in the lowermost stratosphere (70 hPa) and let the model transport this ozone as an inert tracer into the troposphere. We found that this approach overestimates the flux by a factor of 3-4 with the GEOS-1 data, as diagnosed by the simulation of tropospheric ozone concentrations at high latitudes in winter where transport from the stratosphere is a major source. Liu *et al.* [2001] previously found a similar overestimate in a ⁷Be simulation with the GEOS-1 fields; they observed that the overestimate is less with the GEOS-STRAT fields but still of a factor 2-3. We have not yet tried this approach with the GEOS-2 or GEOS-Terra fields.

To overcome the difficulty of excessive stratosphere-troposphere exchange in the GEOS-1 and GEOS-STRAT meteorology fields, we have adopted the Synoz (synthetic ozone) method proposed by McLinden *et al.* [2000] to represent cross-tropopause transport of ozone. In this method, stratospheric ozone is represented by a passive tracer that is released uniformly in the tropical lower stratosphere (between 30°S to 30°N and 70 to 10 hPa) at a rate constrained to match a prescribed global mean cross-tropopause ozone flux. We adopted the total flux of 475 Tg O₃ yr⁻¹ recommended by McLinden *et al.* [2000] and which results in a satisfactory simulation of vertical ozone profiles at mid and high latitudes in winter, as demonstrated below.

3. Model Evaluation

We present here a general evaluation of the model using a simulation conducted for the year 1994. The simulation uses the GEOS-1 fields degraded from 2° × 2.5° horizontal resolution to 4° × 5° for the sake of computational expediency; it includes 20 sigma levels in the vertical, from the surface up to 10 hPa with the lowest levels centered at about 50 m, 250 m, 600 m and 1100 m above the surface for a column based at sea level. A 6-month initialization is conducted from July 1, 1993, to January 1, 1994, and we focus our analysis on the 12-month period for 1994.

Simulated ozone concentrations are evaluated by comparison with 1994 and climatological ozonesonde observations [Logan, 1999]. CO concentrations are evaluated with aircraft observations as well as surface data from Novelli *et al.* [1998]. Other species simulated in the model including hydrocarbons, acetone, NO, PAN, HNO₃, and H₂O₂ are evaluated through comparison with observations from various aircraft missions that have been averaged over chemically

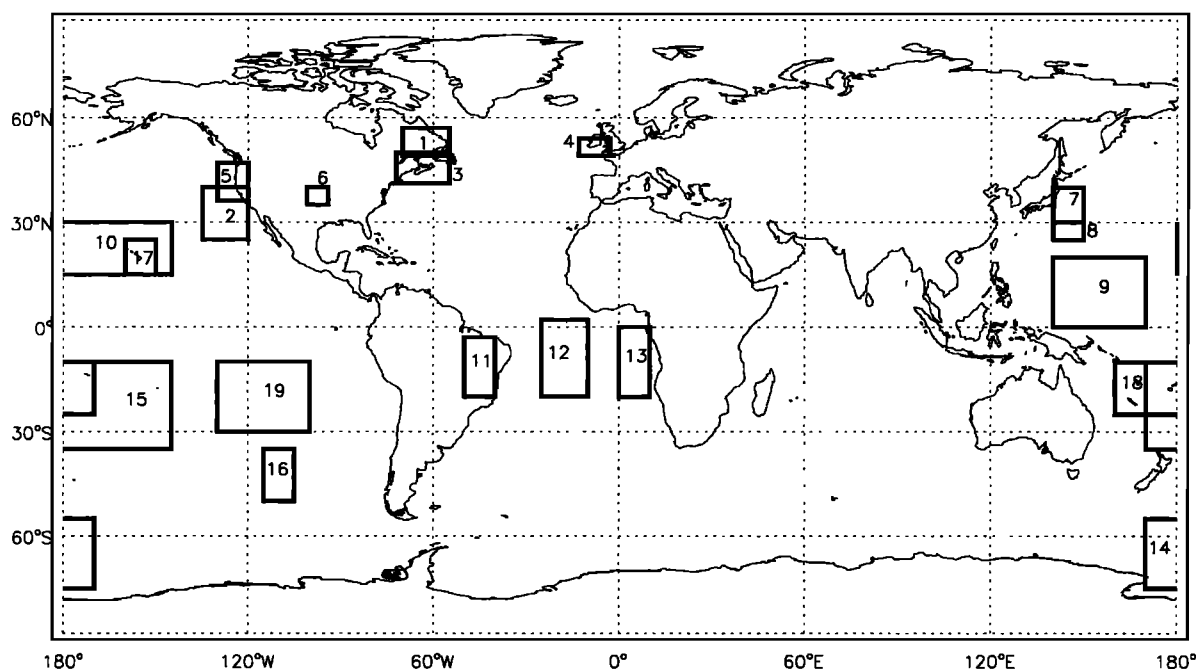

Figure 2. Regions used to aggregate aircraft observations for the purpose of model evaluation. Results are presented for selected regions as listed below. The aircraft mission and the corresponding month used for sampling the model are indicated in parentheses. 1, eastern Canada (July, ABLE 3B); 2, U.S. West Coast (August, CITE 2); 3, Maine (October, SONEX); 4, Ireland (October, SONEX); 5, U.S. West Coast (April, SUCCESS); 6, Kansas (April, SUCCESS); 7, Japan coast (February, PEM-West B); 8, Japan (October, PEM-West A); 9, western Pacific (October, PEM-West A); 10, Hawaii (October, PEM-West A); 11, eastern Brazil (September, TRACE-A); 12, tropical South Atlantic (September, TRACE-A); 13, Africa west coast (September, TRACE-A); 14, Antarctic (September, PEM-Tropics A); 15, tropical South Pacific (September, PEM-Tropics A); 16, south Easter Island (September, PEM-Tropics A); 17, Hawaii (March, PEM-Tropics B); 18, Fiji (March, PEM-Tropics B); 19, Easter Island (March, PEM-Tropics B).

and geographically coherent regions (Figure 2). The regions in Figure 2 are those of Wang *et al.* [1998b] with updates from recent missions (PEM-Tropics A [Hoell *et al.*, 1999], SUCCESS [Toon and Miakelye, 1998], SONEX [Singh *et al.*, 1999], and PEM-Tropics B [Raper *et al.*, 2001]) and are similar to those presented in the data compilation of Emmons *et al.* [2000]. The evaluation presented here uses both observations specific to 1994 and statistics of observations for other years. Clearly, the ability to better constrain the evaluation for a specific year is a major advantage of a model driven by assimilated meteorological observations, and the GEOS-CHEM model has been evaluated in other works with such time-specific observations [Liu *et al.*, 2001; Palmer *et al.*, 2001; Bey *et al.*, this issue]. However, observations available for any given year are limited from a global perspective, and interannual variability is sufficiently small that evaluation with observations for other years is still useful for testing the ability of the model to reproduce general features of global distributions of tropospheric ozone and related species.

3.1. Hydroxyl Radical and Hydrogen Peroxide

Figure 3 shows the zonally averaged 24-hour mean OH concentrations simulated by the model for January and

July. The distribution of OH is in agreement with current knowledge, i.e. concentrations generally maximum in the tropical midtroposphere (reflecting high UV radiation and water vapor) and in summer at 30°N (reflecting anthropogenic enhancement of NO_x and ozone). The maximum values are higher by 10 to 20% than previous global 3-D models [Hauglustaine *et al.*, 1998; Wang *et al.*, 1998b; Mickley *et al.*, 1999]. The higher OH concentrations relative to our own previous models at Harvard appears to result principally from inclusion in the previous radiative calculations of an absorbing aerosol with optical depth of 0.1 at 310 nm varying inversely with wavelength [Logan *et al.*, 1981]. The degree of UV absorption by tropospheric aerosols, in particular organic aerosols, is highly uncertain. In the present simulation we only include absorption by soot particles with a wavelength-independent optical depth of 0.001.

An evaluation of the global mean OH concentrations simulated by the model can be made using the methylchloroform lifetime as a proxy [Spivakovsky *et al.*, 1990; Prinn *et al.*, 1995]. Spivakovsky *et al.* [2000] derived from observations an atmospheric lifetime of 4.6 years for methylchloroform, in close agreement with Prinn *et al.* [1995]. Assuming stratospheric and ocean sinks for methylchloroform with corresponding lifetimes of 43 and 80 years, respectively, Spivakovsky *et al.* [2000] derived an atmospheric lifetime

Figure 3. Zonal mean OH concentrations (10^5 molecules cm^{-3}) simulated in the model for January and July.

of methylchloroform against the tropospheric OH sink of 5.5 years. Wang *et al.* [1998b] and Mickley *et al.* [1999] obtained corresponding lifetimes of 6.2 and 7.3 years in their respective models (note that the methylchloroform lifetimes of 5.1 and 6.2 years reported by Wang *et al.* [1998b] and Mickley *et al.* [1999] were calculated considering only the column of methylchloroform up to 200 hPa and 150 hPa, respectively). In our model the atmospheric lifetime against the tropospheric OH sink is 5.1 years. Our value is lower than that of Spivakovsky *et al.* [2000] but is still within the uncertainty of the estimate.

Observations of H_2O_2 allow an additional evaluation of HO_x radical concentrations ($\text{HO}_x = \text{OH} + \text{peroxy radicals}$) in the model. In most of the troposphere, production of H_2O_2 is the principal sink for HO_x . Figure 4 shows observed vertical profiles of H_2O_2 obtained during several aircraft missions compared to model values for the same geographical region and month. Observed and simulated concentrations both peak at about 2 km, reflecting combined effects of decreasing production with altitude (due to decreasing water vapor) and deposition to the surface. Comparisons for specific regions show significant disagreements, but there is no consistent global bias. The unusually high values observed over Brazil during TRACE-A have been attributed to rapid production in biomass burning plumes [Lee *et al.*, 1997] and are not captured by the model.

3.2. Carbon Monoxide

Simulated monthly mean CO concentrations are compared in Figure 5 with climatological observations in surface air (averaged over 5 to 10 years, depending on the station) as well as observations for 1994. Climatological and 1994 observed values are similar within 10 to 20 ppb except at the Tae-Ahn Peninsula (Korea) where the 1994 data peak at 500 ppb in November while the 6-year mean value peaks only at 300 ppb. The 1994 data for that month consists of only one measurement and can be discarded as anomalous. Observed concentrations are in general higher in the Northern Hemisphere

than in the South Hemisphere, reflecting the stronger anthropogenic sources. The wintertime maximum in the Northern Hemisphere reflects in part low concentrations of OH (the main sink of CO) and in part reduced vertical mixing. The spring maximum in the southern tropics (Ascension Island and Samoa) is due to seasonal biomass burning emissions. At most of the sites, simulated CO concentrations exhibit seasonal variations similar to those of observations (with the exception of the peak at Ascension Island, which occurs a month earlier in the model than in the observations). However, at most of the sites the model underestimates CO concentrations by 10 to 20 ppb (and up to 50 ppb). This is seen also in Figure 6 which shows comparison between vertical profiles of observed and simulated CO concentrations: the observed decrease of CO concentrations with altitude in the Northern Hemisphere and the uniform vertical profiles in the Southern Hemisphere are captured by the model, but the simulated concentrations are systematically too low by 10 to 30 ppb.

This problem of CO underestimate was not present in our previous global 3-D models which used similar inventories [Wang *et al.*, 1998b; Mickley *et al.*, 1999]. It arises from higher concentrations of OH in our model, as discussed in section 3.1. In tests we have found that inclusion of an absorbing aerosol in the radiative transfer calculation could correct the CO discrepancy, but there are no good observational constraints for including such an aerosol. In addition, neither our simulation of methylchloroform lifetime nor our calculated H_2O_2 concentrations show any evident bias relative to observations.

The direct CO emissions used in our model are in agreement with the IPCC [1995] recommendations but are lower than those used in some other global models: For example, Hauglustaine *et al.* [1998] and Granier *et al.* [2000] use a global source of 1218 and 1337 Tg CO yr^{-1} , respectively, while we use a global source of 1043 Tg CO yr^{-1} . The difference is mainly due to natural sources from vegetation and ocean which are poorly known and remain a matter

of speculation. Another uncertain source term for CO is oxidation of NMHC which is estimated by IPCC [1995] to be in the range of 200 to 600 Tg CO yr⁻¹ but in recent models is reported as 647 Tg CO yr⁻¹ [Granier et al., 2000]

and 683 Tg CO yr⁻¹ [Holloway et al., 2000]. Our CO source from NMHC oxidation of 355 Tg CO yr⁻¹ may be too low because the model does not include oxidation of terpenes or higher biogenic hydrocarbons, nor does it include NMHC

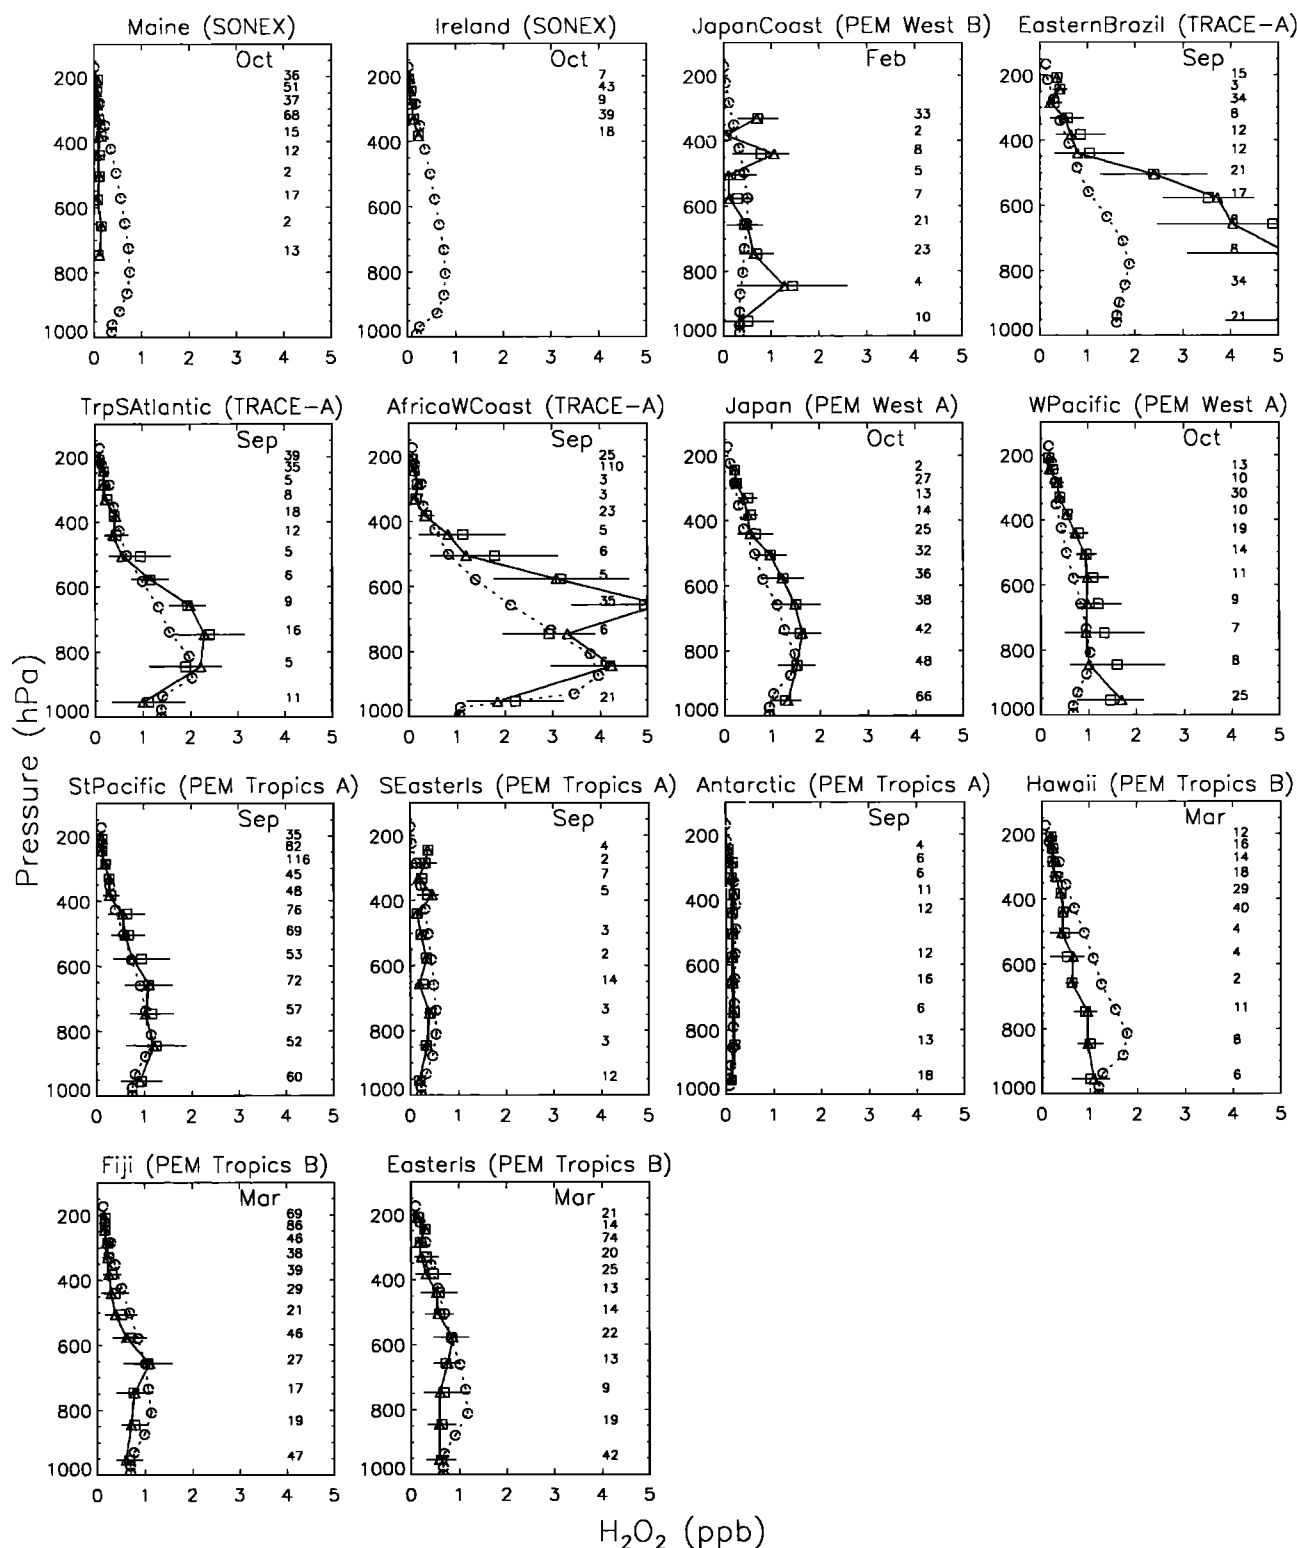

Figure 4. Comparison of observed and simulated vertical profiles of H_2O_2 concentrations. Observations are averaged over the regions in Figure 2. The open squares are mean observed values (with horizontal bars for standard deviations), and the open triangles and solid lines are median observed values. Open circles and dashed lines are simulated values for 1994, sampled over the same region and month.

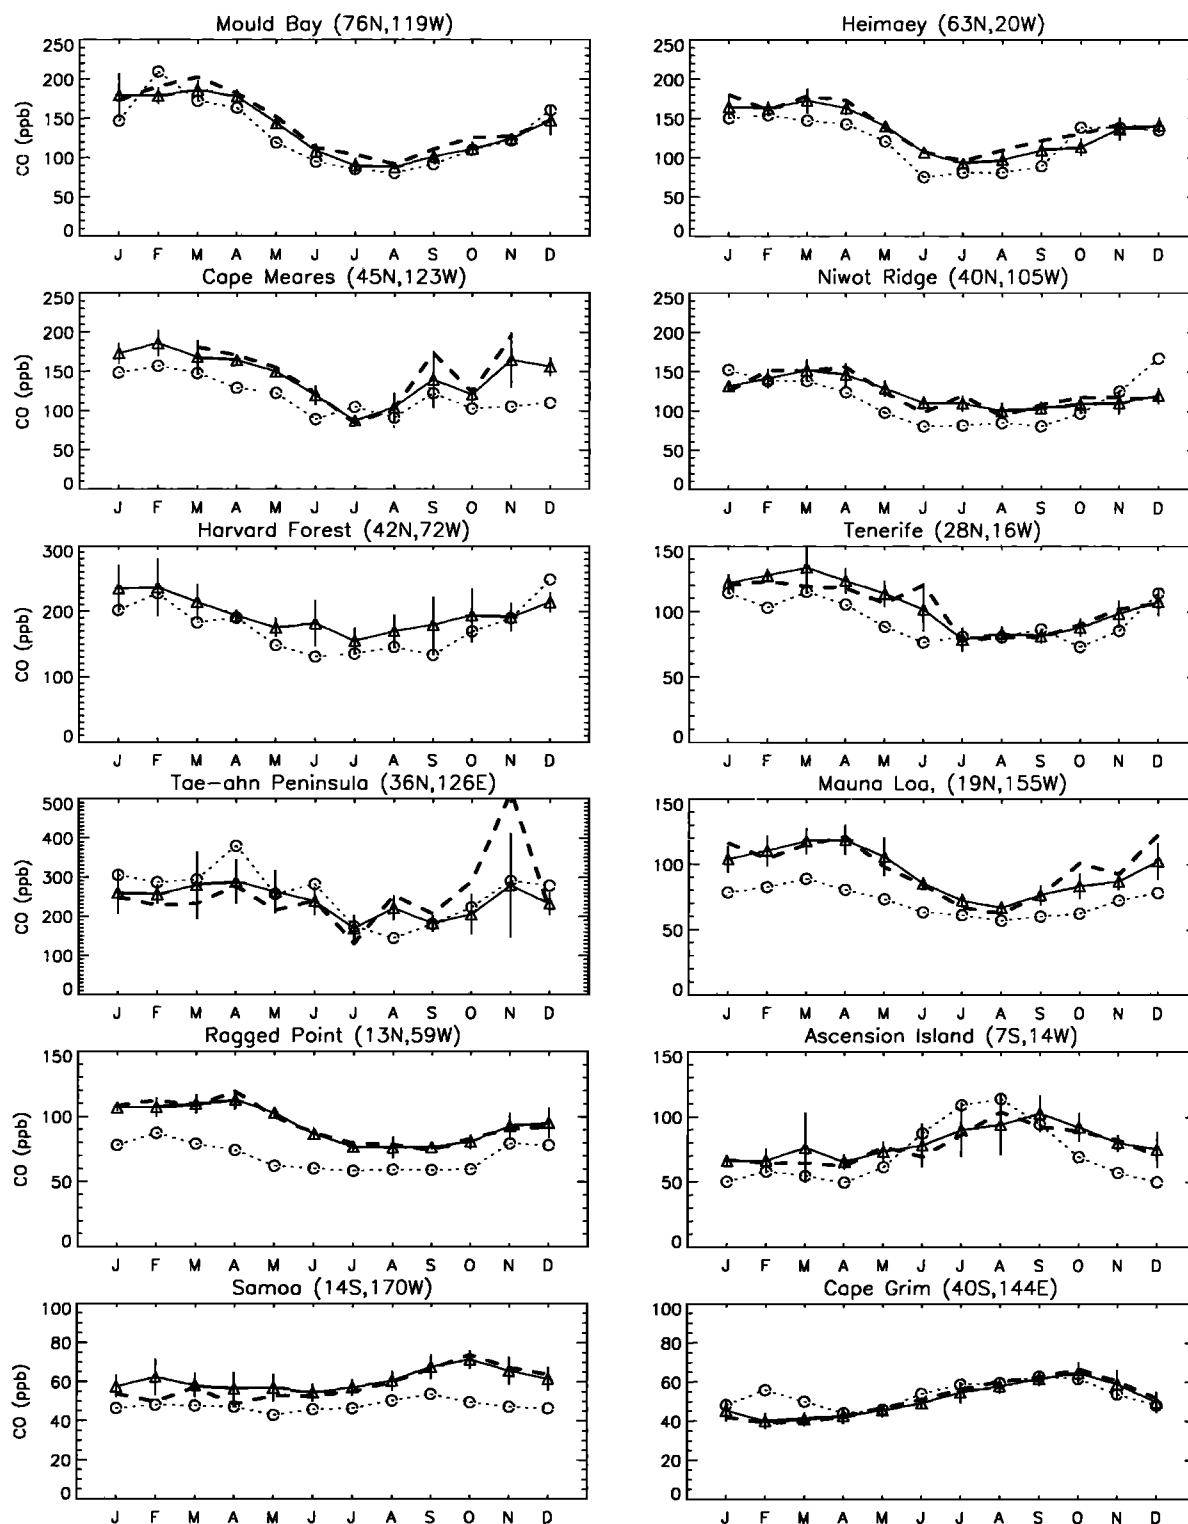

Figure 5. Comparison of observed and simulated monthly mean CO concentrations in surface air. Triangles and solid lines are observed values from *Novelli et al.* [1998] averaged over 5 to 10 years depending on the sites; vertical bars are standard deviations representing interannual variability of the monthly means. Long-dashed lines are the observed values for 1994. Open circles and dashed lines are values from the model for 1994.

emissions from biofuel combustion. Clearly, there are major uncertainties in the sources of CO that could be responsible for our model underestimate of CO concentrations.

3.3. Hydrocarbons and Acetone

Comparison between simulated concentrations and aircraft observations of ethane are shown in Figure 7. Observed

ethane concentrations are usually below 500 ppt at remote sites and in the free troposphere and increase in the boundary layer of regions influenced by anthropogenic pollution or biomass burning. The model reproduces the vertical structures but underestimates observed concentrations, by up to a factor 2 in some regions with high anthropogenic emissions (Maine and Japan Coast) and high biomass burning emis-

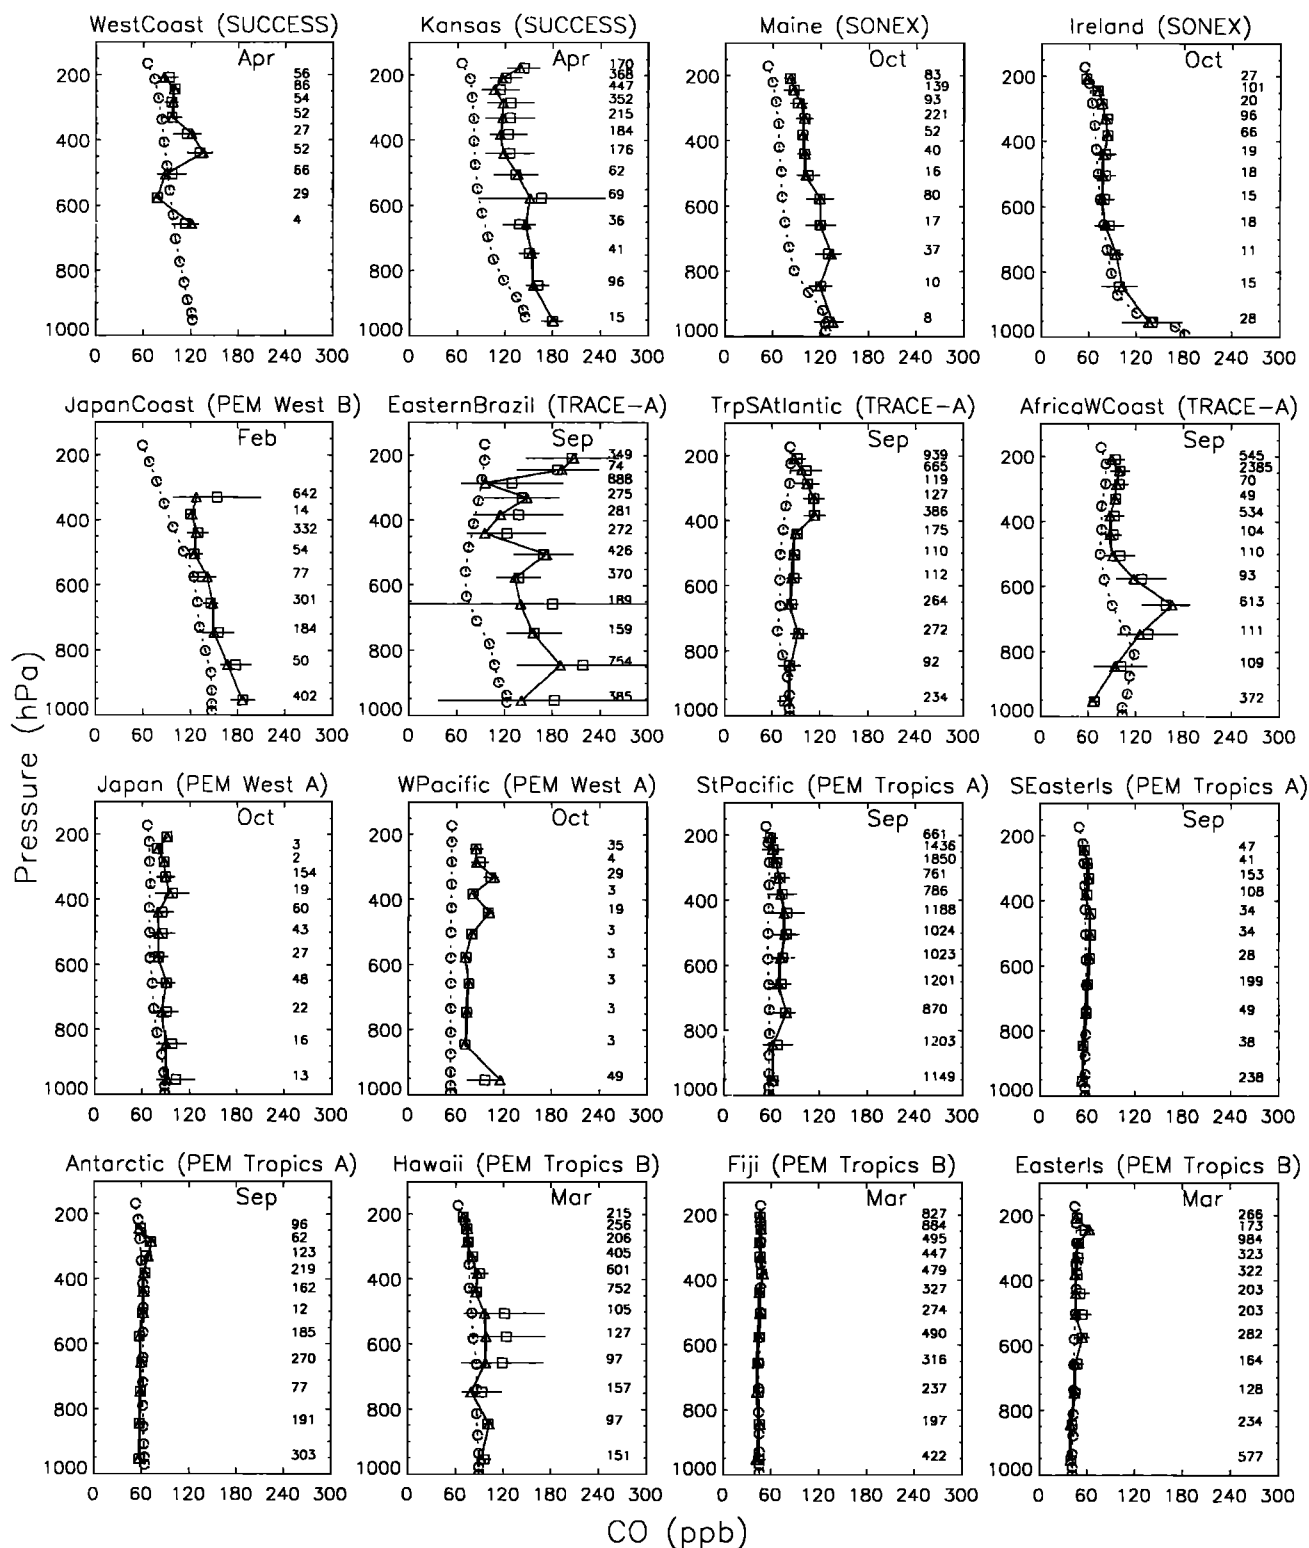

Figure 6. Same as Figure 4, but for CO.

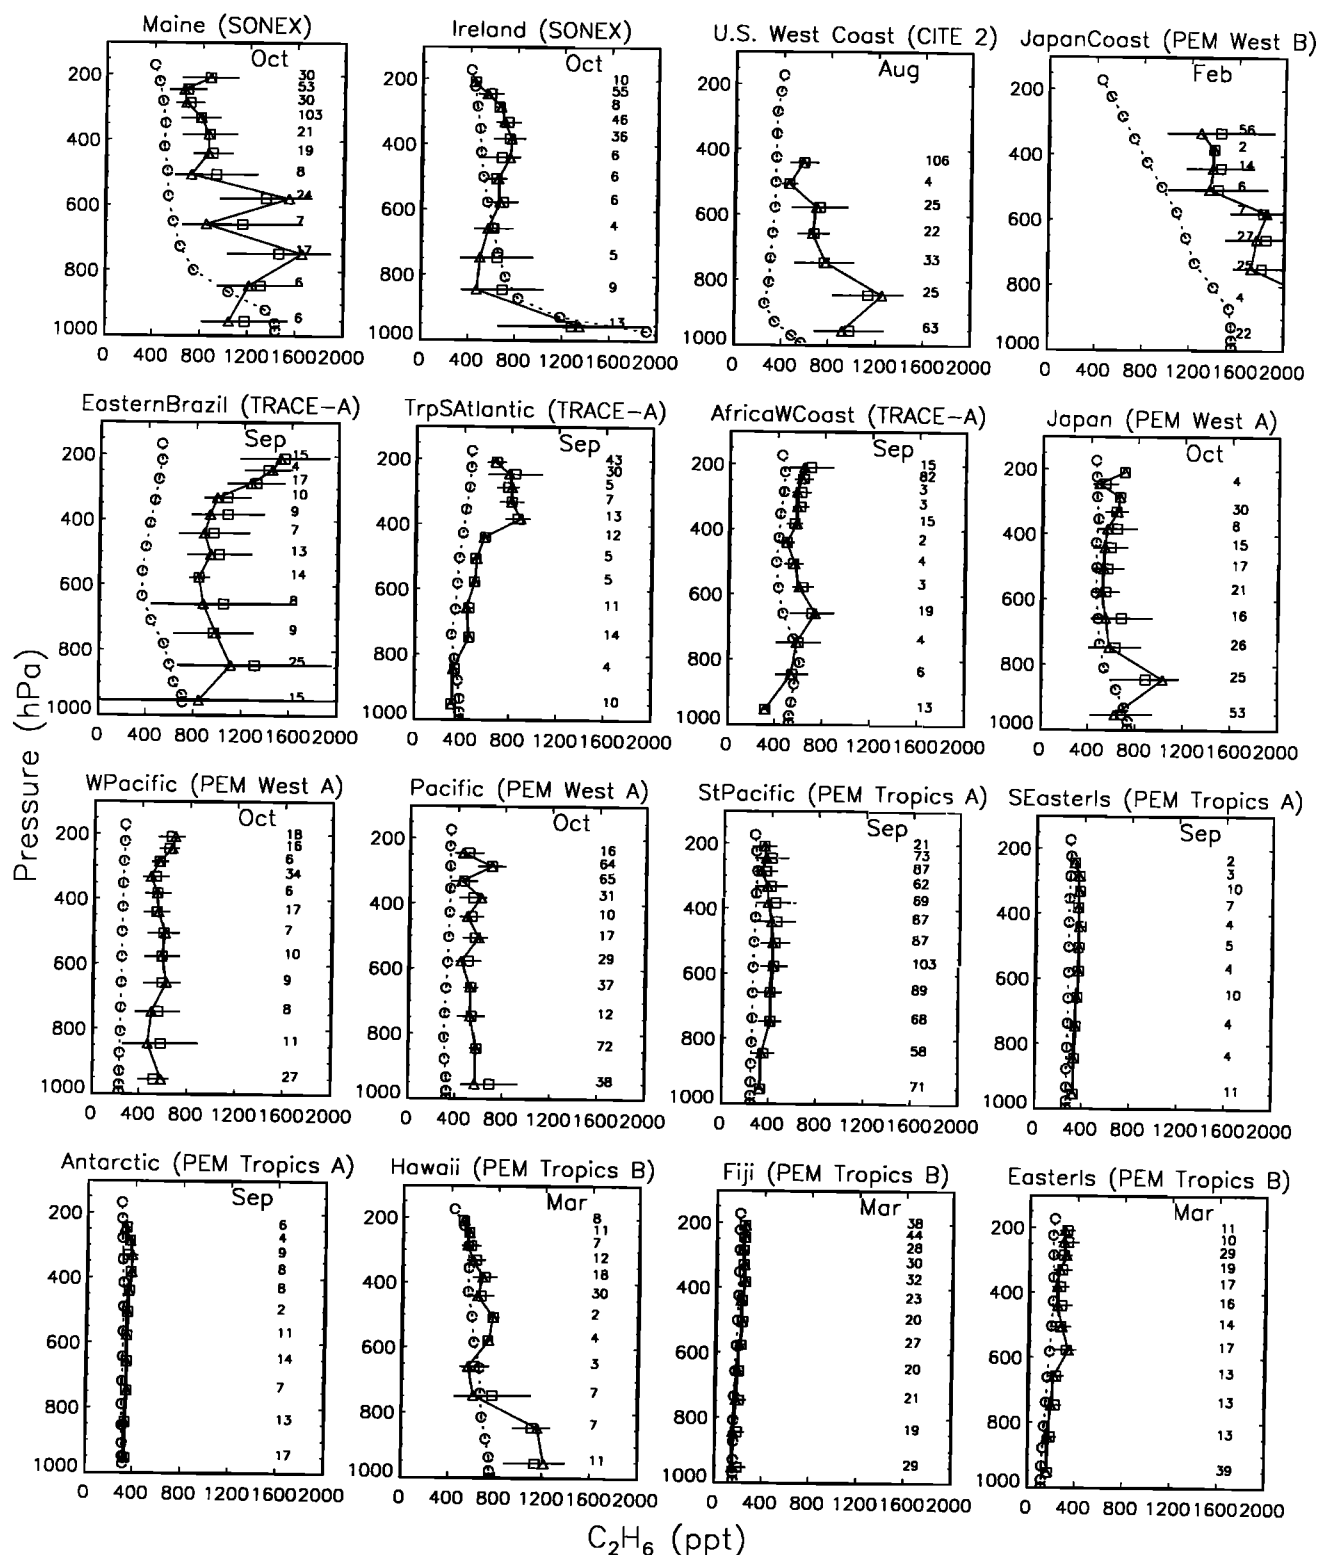

Figure 7. Same as Figure 4, but for ethane.

sions (South Africa and Brazil). A similar underestimate had been previously reported by Wang *et al.* [1998b], thus indicating that this problem is probably not due to our higher OH concentrations but more likely to an underestimate of sources. Model results are too low in regions influenced by

both anthropogenic and biomass burning emissions, which points to a possible underestimate of both categories of emissions.

Global ethane sources of Wang *et al.* [1998b] as well as in our model include 6.6 Tg C yr^{-1} from anthropogenic

activities (mainly natural gas) and 3.0 Tg C yr^{-1} from biomass burning. As pointed out by Wang *et al.* [1998b], this global inventory is lower than previous estimates ($12\text{--}13 \text{ Tg C yr}^{-1}$) from Rudolph [1995]. Biogenic and oceanic sources of ethane are not included in our model. These sources appear to be small [Rudolph, 1995] but could account for 1.6 Tg C yr^{-1} [Hauglustaine *et al.*, 1998] which would represent a 15% increase of our current total inventory. An underestimate of natural gases emissions in the Piccot *et al.* [1992] inventory is a more likely reason for the underestimate, as found in simulations of propane and isobutane (D. J. Jacob *et al.*, Atmospheric budget of acetone, submitted to Journal of Geophysical Research, 2001, hereinafter referred to as Jacob *et al.*, submitted manuscript, 2001).

Figure 8 shows a comparison between simulated monthly means and aircraft observations of isoprene concentrations. Observed values show a strong gradient in the boundary layer, decreasing from about 1 ppb near the surface to less than 0.05 ppb at 3 km at most of the sites. This vertical structure as well as the overall magnitudes of concentrations are captured by the model, lending some support to our estimate of isoprene emission (397 Tg C yr^{-1} globally). The C-shaped profiles simulated over the southeastern United States in summer reflect convective pumping to the middle troposphere, but no observations are available to test this model feature.

Figure 9 compares observed and modeled vertical profiles for acetone. Model results in midlatitudes (Maine and

Ireland) agree fairly well with the observations. In eastern Canada, the model underestimates observed values by a factor 2, a problem previously reported by Wang *et al.* [1998b]. Scaling acetone emissions to monoterpene emissions (as is done in the current version of the GEOS-CHEM model) rather than isoprene emissions (as was done in Wang *et al.* [1998a, 1998b]) did not correct this underestimate. The model underestimates by a factor of 2–3 observed acetone concentrations over the South Pacific in fall (PEM-Tropics B aircraft mission). Matching these observations would require either a large dispersed secondary source of acetone or a large oceanic emission [Singh *et al.*, 2000b]. An inverse analysis of acetone sources and sinks using the GEOS-CHEM model is presented by D. J. Jacob *et al.* (submitted manuscript, 2001).

3.4. Nitrogen Species

Comparison of observed and simulated NO and PAN concentrations are shown in Figure 10 and Figure 11. The model typically reproduces NO concentrations within a factor of 2. High NO concentrations over southern Africa and the South Atlantic are due to biomass burning and lightning [Jacob *et al.*, 1996; Pickering *et al.*, 1996]. Lower concentrations are observed elsewhere in the tropics, and again these are well captured by the model. The most severe discrepancy is an overestimate of NO concentrations in the upper troposphere over Hawaii and Fiji during PEM-Tropics B. As discussed

Figure 8. Same as Figure 4, but for isoprene. Data from the "Peru" region are from Helmig *et al.* [1998]; data from the "Tennessee" region are from Guenther *et al.* [1996]; data from the "Southern U.S." region are from Andronache *et al.* [1994].

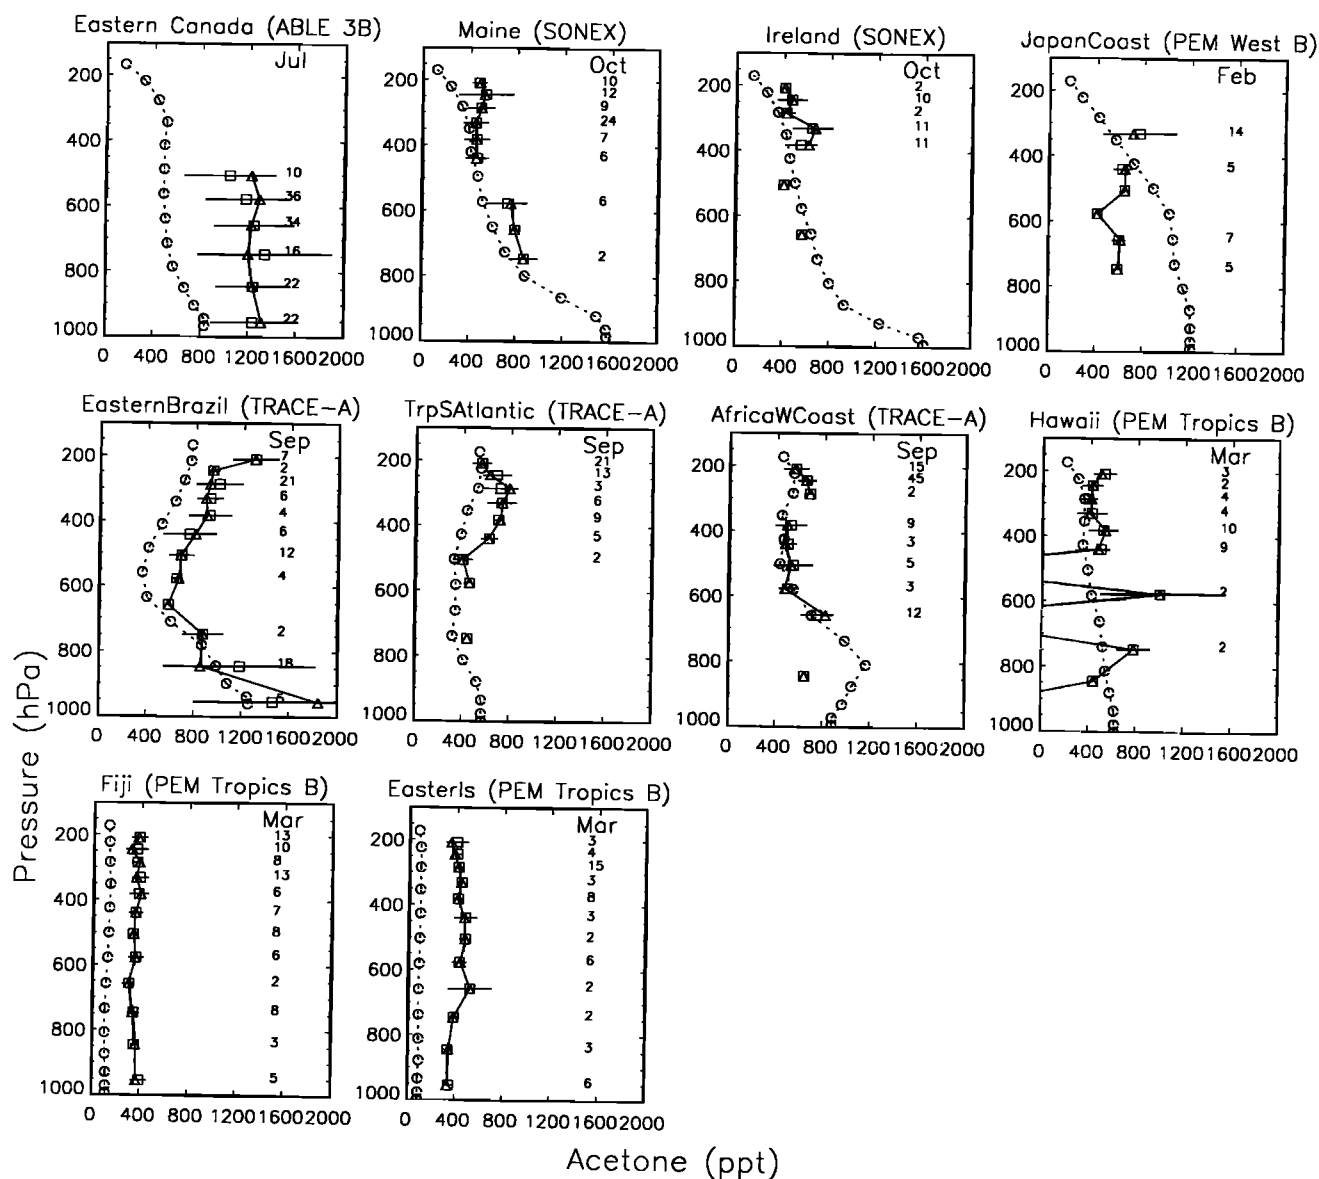

Figure 9. Same as Figure 4, but for acetone.

by Wang *et al.* [2001], these observations were made under conditions of particularly intense marine convection when low- NO_x air from the marine boundary layer is pumped frequently to the upper troposphere.

Peroxyacetylnitrate (PAN) is a reservoir species for NO_x produced by oxidation of organic compounds. Observed PAN concentrations are high over the continental regions (especially where influenced by biomass burning or fossil fuel emissions) and low in regions remote from direct NO_x sources. The model captures similar trends. Simulated concentrations at northern midlatitudes are consistent with observed values although the model overestimates PAN concentrations over Japan in October, a problem previously noted by Wang *et al.* [1998b]. Simulated PAN concentrations for the TRACE-A region, which was heavily impacted by biomass burning, are high but still underestimate observations. Such underestimate was previously noted for ethane and may reflect insufficient NMHC emission from biomass burning in the model.

Nitric acid (HNO_3) is produced in the atmosphere by reaction of NO_2 with OH and by hydrolysis of N_2O_5 in aerosols. Major sinks are dry and wet deposition. Comparison of model results with observed HNO_3 concentrations is shown in Figure 12. The model typically overestimates the observations by a factor of 2-3. This problem is common to most current global 3-D models of tropospheric chemistry [Wang *et al.*, 1998b; Hauglustaine *et al.*, 1998; Mickley *et al.*, 1999; Lawrence *et al.*, 1999]. The partitioning of HNO_3 into aerosols might provide an explanation since the model does not differentiate between gaseous and aerosol nitrate. There is also strong evidence that the model underestimates precipitation scavenging in the upper troposphere, as shown by Liu *et al.* [2001] in a simulation of ^{210}Pb and ^7Be tracers. Lawrence and Crutzen [1998] suggested that cirrus precipitation could lead to a considerable scavenging of HNO_3 from the upper troposphere. This process is not represented in our model. (They also suggested that cirrus precipitation would scavenge H_2O_2 ; however, that seems

dubious since H_2O_2 is only weakly partitioned into the cirrus ice phase [Mari et al., 2000].)

3.5. Ozone

Evaluation of simulated ozone concentrations uses the multiyear climatology of ozonesonde data presented by Logan [1999] as well as 1994 ozonesonde measurements.

Figure 13 compares simulated and observed seasonal variations of ozone concentrations at 300, 500, and 800 hPa. Where available, 1994 seasonal variations are also reported. The 1994 observations are usually within 20 ppb of the climatology, with the exception of high latitudes at 300 hPa where small shifts in tropopause height can introduce considerable variability in ozone; model evaluation is not

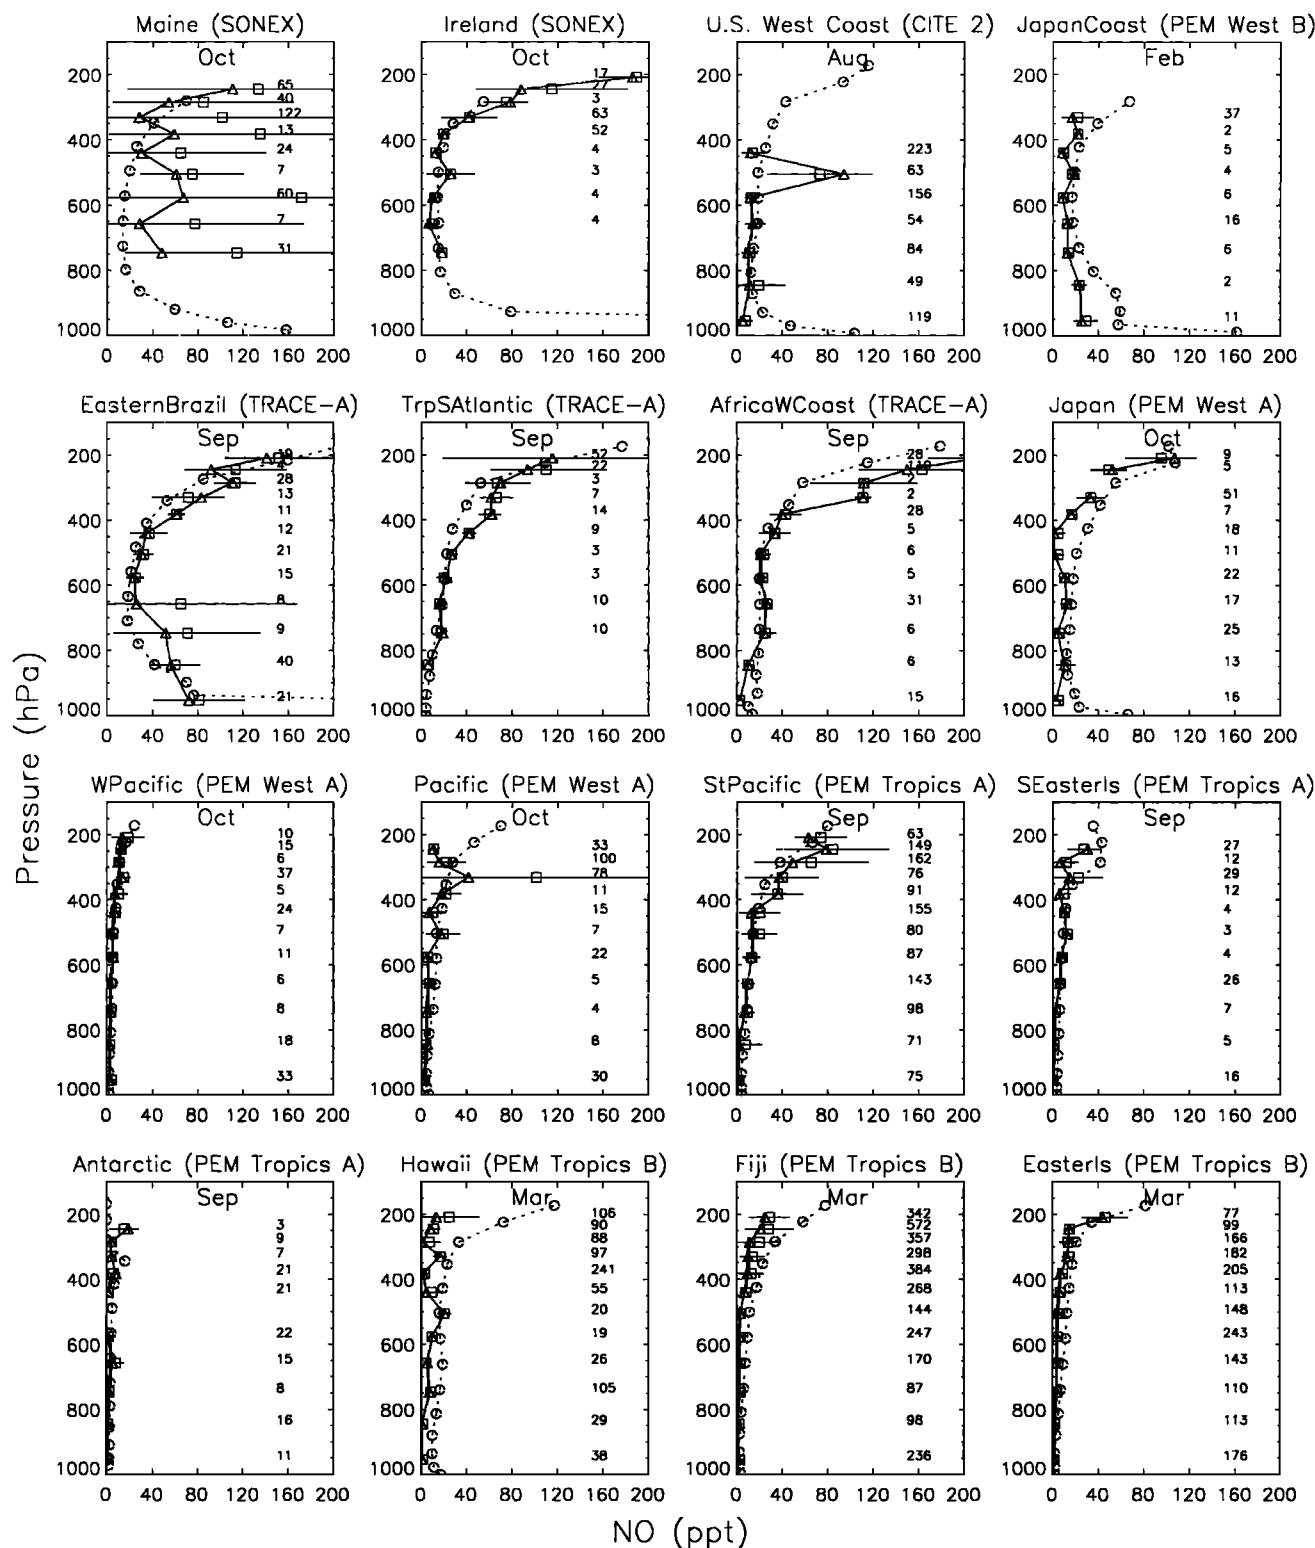

Figure 10. Same as Figure 4, but for NO.

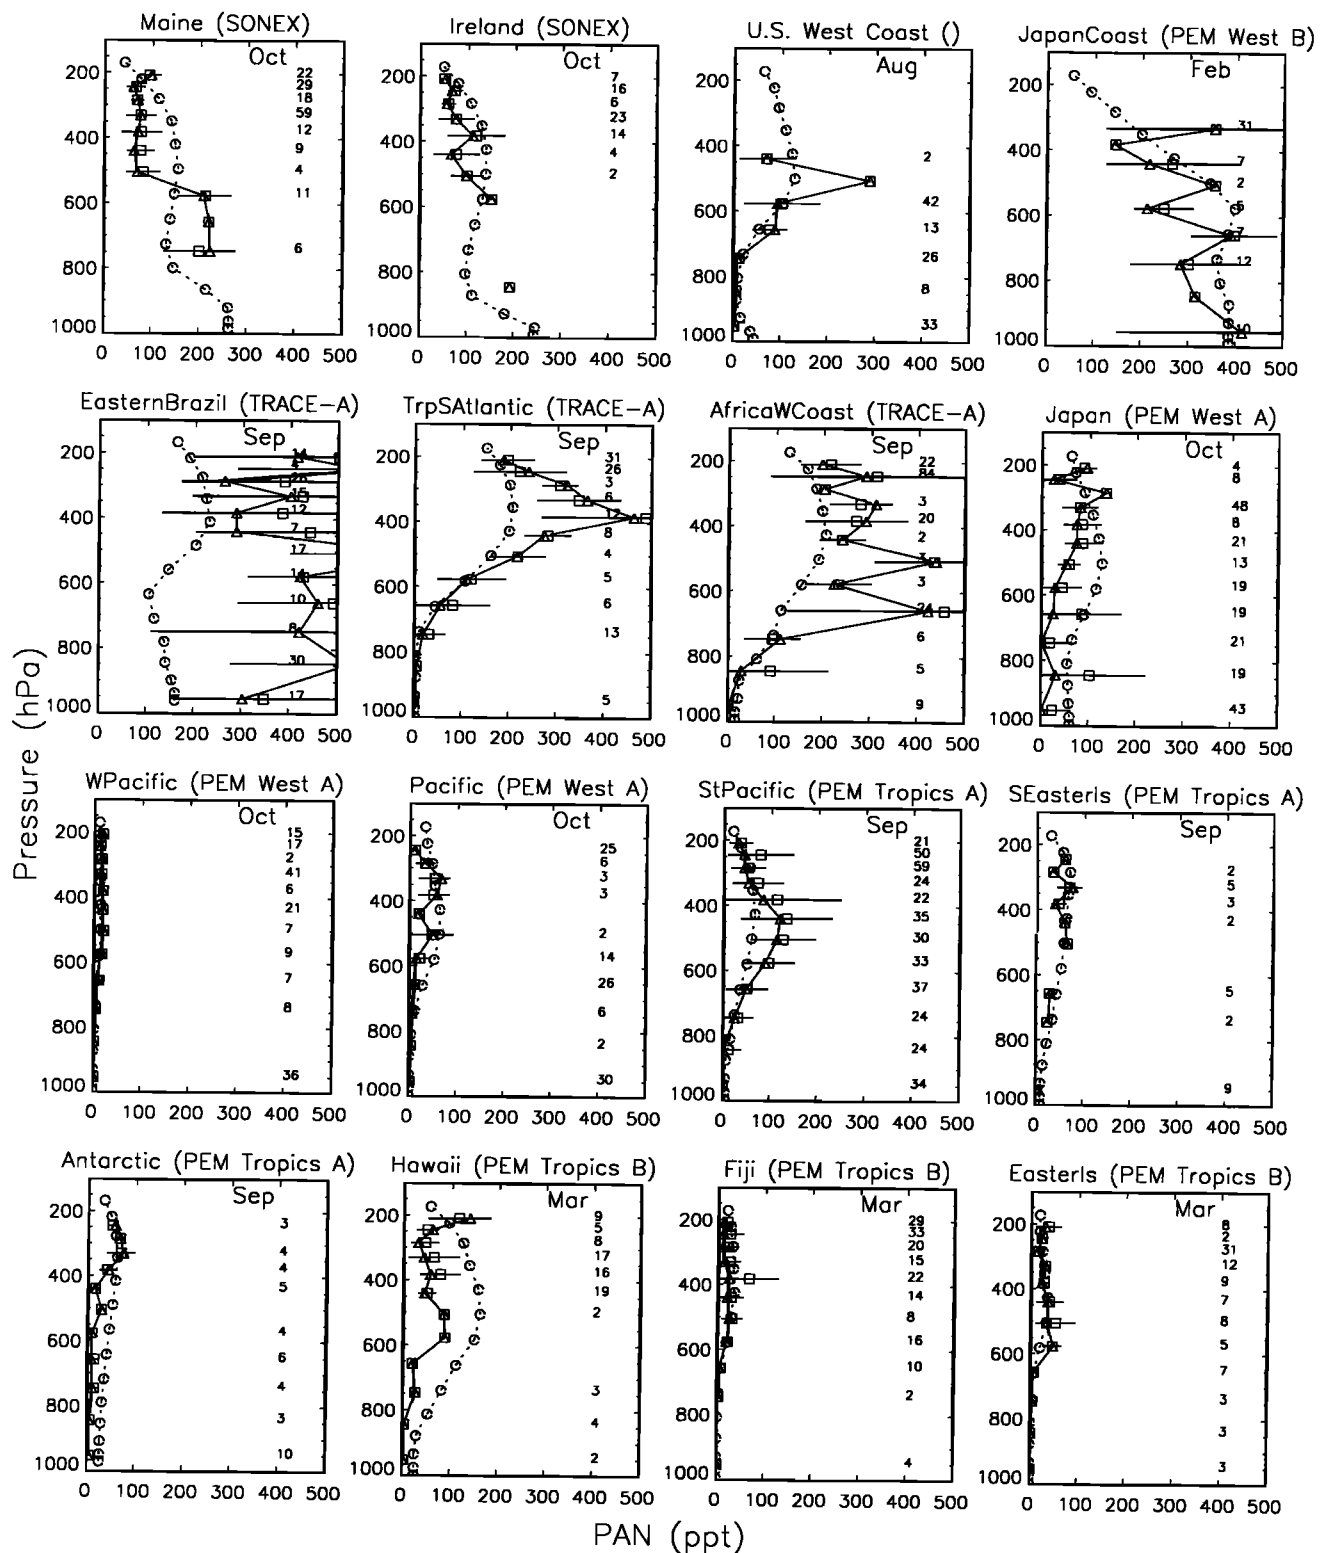

Figure 11. Same as Figure 4, but for PAN.

well constrained at 300 hPa because of this high variability.

The distribution and seasonal variation of tropospheric ozone in the climatology is described in detail by Logan [1999]. With a few exceptions, model results are within 10

ppb of the observed values and have the correct seasonal phase. At high northern latitudes the model captures the spring maximum in the lower troposphere and the maximum from May to August in the middle troposphere. Seasonal

variations at northern midlatitudes are relatively well represented. However, the model tends to underestimate slightly the amplitude of the seasonal variation in the extratropics (Hohenpeissenberg and Saporro for example), a problem which we ascribe tentatively to insufficient seasonal vari-

ation of cross-tropopause transport (less than that shown by Wang *et al.* [1998a]). Elevated concentrations at 800 hPa at Boulder in summer are likely due to pollution from Denver, which we do not capture well in the model. Good simulation is usually achieved in the tropics and subtropics

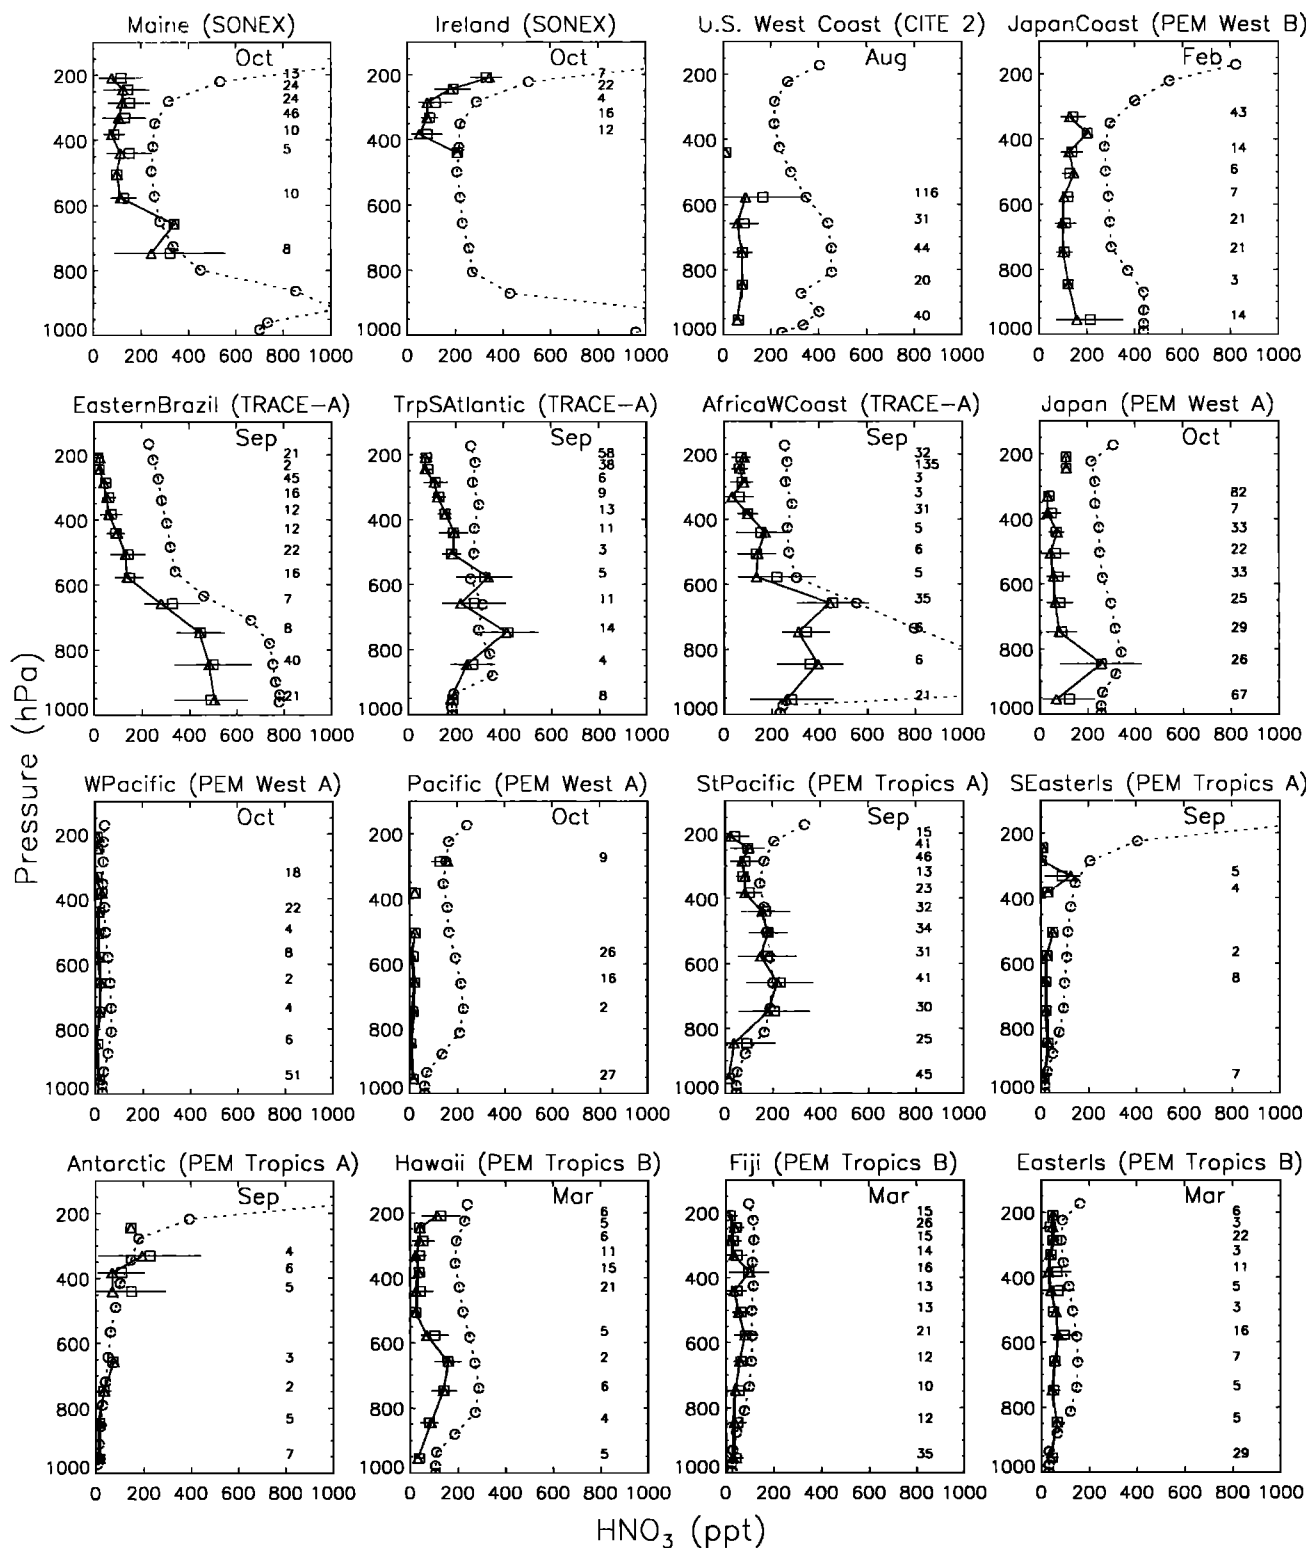

Figure 12. Same as Figure 4, but for HNO_3 .

Figure 13. Comparison of observed and simulated monthly mean concentrations of ozone at 800, 500, and 300 hPa. Observations (open triangles and solid lines) are from the ozonesonde climatology of Logan [1999]; vertical bars are standard deviations corresponding to interannual variability. Long-dashed lines are the observed values for 1994 (there are no observations in 1994 at Samoa and Natal). Model values (open circles and dashed lines) are for 1994.

to within the constraints offered by the observations. The observed minima in eastern Asia (Kagoshima and Naha) due to the summer monsoon are captured by the model. The spring maximum and summer minimum observed in the northern subtropics (Hilo, for example) are well represented by the model throughout the troposphere. Observations in the southern tropics (Natal) show a large austral spring

maximum due to biomass burning emissions that the model captures well. The longitudinal gradient observed in the southern tropics between Natal and Samoa is also well captured.

Table 5 gives the global budget of tropospheric ozone in the model. The global photochemical production and destruction rates of ozone are 4900 Tg yr^{-1} and 4300 Tg

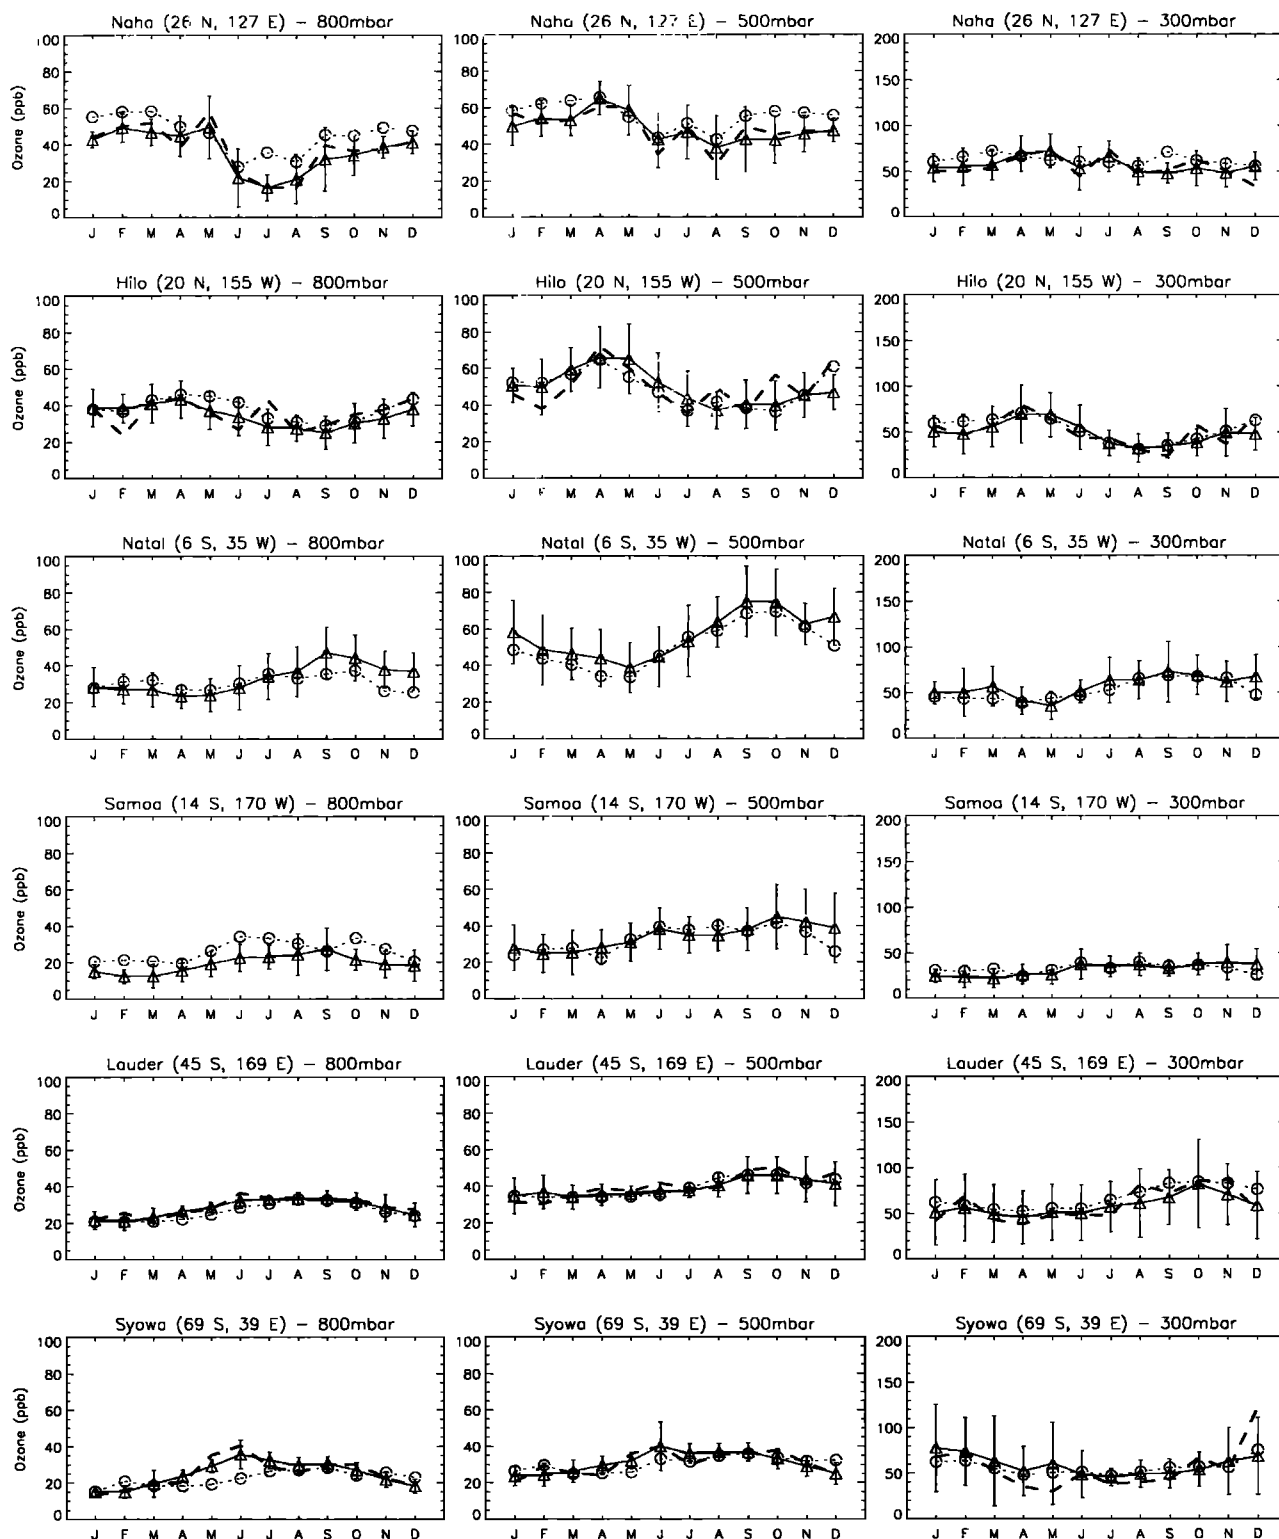

Figure 13. (continued)

Table 5. Global Budget for Tropospheric Ozone in the GEOS-CHEM Model

	Global	Northern Hemisphere	Southern Hemisphere
Sources, Tg O ₃ yr ⁻¹			
Chemical production	4900	3100	1800
Stratospheric influx	470	280	190
Total	5370	3380	1990
Sinks, Tg O ₃ yr ⁻¹			
Chemical loss	4300	2600	1700
Deposition	1070	740	330
Total	5370	3340	2030
Burden, Tg O ₃	315	175	140

The budget is for the extended odd oxygen family defined as O₃ + NO₂ + 2×NO₃ + PAN + PPN + MPAN + HNO₄ + HNO₃ + 3×N₂O₅ and applies to the column up to the model tropopause. Values are annual means for 1994.

yr⁻¹, respectively, with a stratospheric input of 470 Tg yr⁻¹. Previous global 3-D models indicate photochemical production ranging from 3314 to 4550 Tg yr⁻¹ and photochemical loss ranging from 2511 to 4065 Tg yr⁻¹ [WMO, 1998; Lelieveld and Dentener, 2000]. Stratospheric inputs in these models vary from 390 to 768 Tg yr⁻¹ [WMO, 1998]. Our calculated values for the photochemical terms are at the high end of previous models. They are in particular higher than in our previous global 3-D models at Harvard; Mickley *et al.* [1999] and Wang *et al.* [1998b] report production rates of 4330 and 4100 Tg yr⁻¹ and loss rates of 3960 and 3680 Tg yr⁻¹, respectively. The difference appears to reflect the stronger UV actinic fluxes in the present model, as discussed previously.

4. Conclusion

This paper provided a first description of GEOS-CHEM, a global 3-D model of tropospheric chemistry driven by GEOS assimilated meteorological fields from the NASA Data Assimilation Office (DAO). A 1-year simulation is presented for 1994, and results are evaluated with observations both for 1994 and for other years. We show that the model is capable of representing the general features of the global distributions of tropospheric ozone and related species although there are some significant discrepancies.

Global chemical production and loss rates of tropospheric ozone, as well as global OH concentrations, are at the high end of values previously reported in global 3-D models including earlier generations of our 3-D model at Harvard. This difference appears largely due to our suppression of an UV-absorbing background aerosol (with an optical depth of 0.1 at 310 nm) that was present in the earlier models. Although organic aerosols in the troposphere are expected to absorb UV radiation, there are no observations available to usefully constrain the corresponding optical depth at the wavelengths of interest. The present model can accommodate the observed methylchloroform lifetime and H₂O₂ concentrations (which provide standard tests of photochemical activity for global models) within the constraints provided by these observations. However, that does not exclude model OH for possibly being too high by ~20%.

The model systematically underestimates observed CO concentrations by 10–30 ppb, which could reflect a problem with current source inventories as well as an overestimate of OH. Simulation of ethane indicates an underestimate of sources. The large underestimate of acetone concentrations over the South Pacific suggests a large oceanic source. Simulated concentrations of NO and PAN are generally within a factor of 2 of observed values (often much better) and show the correct vertical structure. The model overestimates HNO₃ concentrations by factors of 2–3 in the remote troposphere, a problem which we attribute in part to insufficient scavenging.

The model reproduces well the global distribution of tropospheric ozone concentrations as determined from ozonesonde observations. It simulates usually to within 10 ppb the 1994 observations as well as the multiyear climatology (which are similar except near the tropopause). It captures the observed seasonal phases and amplitudes in different regions of the troposphere. There is a slight underestimate in the amplitude of the seasonal variation in the extratropical Northern Hemisphere which we attribute to insufficient seasonal variation in the parameterized cross-tropopause ozone flux.

In a companion paper [Bey *et al.*, this issue], we use the GEOS-CHEM model to examine the Asian outflow of ozone, CO, and NO_y species over the western Pacific by simulation of observations from the PEM-West B aircraft mission in February–March 1994.

Acknowledgments. This research was supported by the NASA Atmospheric Chemistry Modeling and Analysis Program (ACMAP) and by the NASA Earth Observing System (EOS). We wish to thank Clarissa Spivakovsky for very helpful discussions. We are grateful to Andrew Fusco for processing isoprene observations.
